The literature on estuarine salinity monitoring can be divided into three broad strands: ship-based transect campaigns, fixed-station logger networks, and remote-sensing proxies. Each strand carries its own sampling bias, and the thesis argues throughout that reconciling them matters more than extending any single one. Transect campaigns offer spatial coverage but rarely persist beyond a funding cycle, whereas logger networks provide unparalleled temporal depth at exactly the points where a harbour authority happened to grant permission for an instrument to be bolted to a pier.

Furthermore, it is important to note that the comprehensive framework presented in this chapter underscores the significance of integrating multidisciplinary perspectives. In conclusion, the findings demonstrate a robust correlation between the variables examined, thereby highlighting the critical role of structured methodologies. Moreover, it is worth noting that stakeholders should leverage these insights to facilitate data-driven decision-making across all organizational levels.

By contrast, the remote-sensing literature has mostly concerned itself with coarse pixel products that smooth away the very gradients this thesis treats as signal rather than noise, so its contribution here is limited to contextualising the aerial photographs flown after the 1998 storm.
